Discrete source coding

Cédric RICHARD Université Côte d'Azur

# DISCRETE SOURCE CODING

Each of the Q states  $s_i$  of source S is associated with a codeword, that is, a sequence of  $n_i$  symbols of a q-ary alphabet. These constitute a source code that can be noted as follows:  $C = \{c_1, \ldots, c_q\}$ .

### **Example.** The Morse code

- > quaternary code (dot, dash, long space, short space)
- $\triangleright$  variable length code
- ▷ the shortest sequence is for "E"

# **PROBLEM**

Source coding and adaptation (ideal noiseless channel)

Let S be a source characterized by a rate  $D_s$  (Q-ary symbol per second). Consider a noiseless channel with maximum rate  $D_c$  (q-ary symbol per second). We define:

- emission rate of the source :  $T \triangleq D_s H(S)$
- channel capacity :  $C \triangleq D_c \log q$

If T > C: the channel cannot transmit the information

If  $T \leq C$ : the channel can theoretically transmit the information

If we have a q-ary code where the average length  $\overline{n}$  of codewords is such that  $\overline{n} D_s \leq D_c$ , then this code can be used for transmission.

Otherwise, how to encode the source words to make their transmission possible?

Source coding is used to eliminate redundant information WITHOUT LOSS!!!

General model

A discrete source S is defined by an alphabet  $\mathcal{A} = \{s_1, \ldots, s_Q\}$  and an emission mechanism. It is a discrete-time random process

$$S_1, \ldots, S_{i-1}, S_i, S_{i+1}, \ldots$$

characterized by joint laws:

$$P(S_1,\ldots,S_n), \forall n \in \mathbb{N}^*$$

> model too general to give rise to tractable developments

#### Complementary assumptions

For simplicity, assumptions need to be made about the source.

**Property 1** (Stationary process). A random process  $S_i$  is said to be stationary if the laws that govern it are independent of the origin of time, that is,

$$P(S_1 = s_{i_1}, \dots, S_n = s_{i_n}) = P(S_{n_0+1} = s_{i_1}, \dots, S_{n_0+n} = s_{i_n}),$$

for all positive  $n_0$  and n.

**Example.** A memoryless source is characterized by independent and identically distributed  $S_i$ . This is a stationary process.

$$P(S_1 = s_{i_1}, \dots, S_n = s_{i_n}) = P(S = s_{i_1}) \dots P(S = s_{i_n}).$$

#### Complementary assumptions

Again, for the sake of simplicity, the following ergodicity assumption can be made.

**Property 2** (Ergodic process). A stationary random process  $S_i$  is ergodic if, for every k = 1, 2, ..., for every set of indices  $i_1, ..., i_k$  and for any bounded function  $f(\cdot)$  from  $\mathcal{A}^k$  into  $\mathbb{R}$ , we have:

$$\frac{1}{n}\sum_{k=1}^n f(S_{i_1},\ldots,S_{i_k}) \xrightarrow{a.s.} E\{f(S_{i_1},\ldots,S_{i_k})\}.$$

Interest. An ergodic process can be studied by observing any long enough trajectory.

#### Markov source

Any source S emits symbols according to a law that can depend on all past symbols.

**Definition 1** (Markov source). A source S is said to be Markovian if

$$P(S_{n+1} = s_{i_{n+1}} | S_n = s_{i_n}, \dots, S_1 = s_{i_1}) = P(S_{n+1} = s_{i_{n+1}} | S_n = s_{i_n})$$

for all  $s_{i_1}, \ldots, s_{i_{n+1}}$  in A.

only depends on the one previous time instance. This propagation is from one time stamp to next one.

As a direct consequence we have

$$P(S_1, ..., S_n) = P(S_1) P(S_2|S_1) ... P(S_n|S_{n-1})$$

one only need to know the probability of one state given the previous state

#### Markov source

**Definition 2** (Time invariance). A Markov source S is time-invariant if, for all  $n \in \{1, 2, \ldots\}$ , we have

$$P(S_{n+1}|S_n) = P(S_2|S_1)$$

Such a source is entirely defined by the vector of initial probabilities  $p|_{t=0}$  and the transition  $\Pi$  whose entries are

$$\Pi(i,j) = P(S_2 = s_j | S_1 = s_i)$$

Obviously, we have  $\sum_{j=1}^{q} \Pi(i,j) = 1$  et  $\Pi(i,j) \geq 0$ .

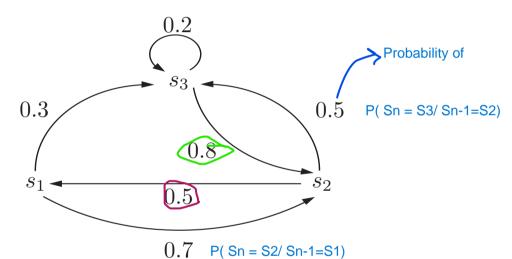

Example of Markov source

Consider the following Markov source

probability to stay in the same state

P(Sn = S3/Sn-1=S3)

The corresponding transition matrix can be written as:

 $\Pi = \begin{pmatrix} 0 & 0.7 & 0.3 \\ \hline 0.5 & 0 & 0.5 \\ \hline 0 & 0.8 & 0.2 \end{pmatrix}$ 

Row Column

1.

P(Sn = j / Sn-1 = i)

#### Markov source in steady state

**Definition 3** (steady-state - version 1). Consider a Markov source S. If it exists, its steady state distribution is defined as:

$$\lim_{n \to \infty} P(S_n = s_i)$$

for all  $i \in \{1, ..., Q\}$ .

Let  $p|_{t\to\infty}$  the steady-state distribution if it exists. Given that  $p|_{t=n}=p|_{t=n-1}\Pi$ , we have:

$$p|_{t\to\infty} = p|_{t\to\infty} \Pi$$

We say that  $p|_{t\to\infty}$  is the steady-state distribution of S since initializing it with  $p|_{t\to\infty}$  makes it stationary.

**Drawback.** The steady state defined in this way depends on the initial distribution  $p|_{t=0}$ . Other definitions exist.

Markov source in steady state

**Definition 4** (steady-state - version 2). Consider a Markov source S. If it exists, its steady state distribution is defined as:

$$\lim_{n \to \infty} P(S_n = s_i | S_1 = j)$$

for all  $i, j \in \{1, ..., Q\}$ .

Main interest. The asymptotic behavior of S is independent of the initial distribution.

m-th order Markov source

A Markov source is characterized by a memory of size m = 1. This can be generalized to memory sizes m > 1.

**Definition 5** (*m*-th order Markov source). A source S is an *m*-th order Markov source if:

$$P(S_{n+1} = s_{i_{n+1}} | S_n = s_{i_n}, \dots, S_1 = s_{i_1})$$

$$= P(S_{n+1} = s_{i_{n+1}} | S_{n-m} = s_{i_{n-m}}, \dots, S_n = s_{i_n})$$

for all  $s_{i_1}, \ldots, s_{i_{n+1}}$  in A.

**Remark.** Any m-th order Markov source S can be expressed as a 1-st order Markov source by considering an m-th order extension of S.

Entropy of a stationary source

Any source S emits symbols according to a law that can depend on the symbols that came before them. The definition of the entropy of S must take this into account.

**Definition 6** (Entropy of a stationary source - version 1). The entropy of a stationary S source is defined as:

$$H_0 \triangleq \lim_{n \to +\infty} H(S_n | S_1, \dots, S_{n-1}).$$

This definition only makes sense if the limit exists.

Entropy of a stationary source

Validation of the definition. One need to check that the following limit exists:

$$\lim_{n \to +\infty} H(S_n | S_1, \dots, S_{n-1})$$

We have:

$$0 \le H(S_n|S_1, S_2, \dots, S_{n-1}) \le H(S_n|S_2, \dots, S_{n-1}) \le \dots \le H(S_n).$$

Since S is stationary, we can write:

$$H(S_n) = H(S_1)$$
  $H(S_n|S_{n-1}) = H(S_2|S_1)$  ...

The above inequality can be replaced by:

$$0 \le H(S_n|S_1,\ldots,S_{n-1}) \le H(S_{n-1}|S_1,\ldots,S_{n-2}) \le \ldots \le H(S_1).$$

The series  $\{H(S_n|S_1,\ldots,S_{n-1})\}_{n\geq 1}$  is decreasing and bounded. It is therefore convergent, ensuring the validity of the definition in the stationary case.

Entropy of a stationary source

**Definition 7** (Entropy of a stationary source - version 2). The entropy of a stationary S source is defined as:

$$H_0 \triangleq \lim_{n \to +\infty} \frac{H(S_1, \dots, S_n)}{n}.$$

Both definitions are equivalent in the case of stationary sources. Indeed, it results from the following equality:

$$H(S_1, \dots, S_n) = H(S_1) + H(S_2|S_1) + \dots + H(S_n|S_1, \dots, S_{n-1})$$

that  $H(S_1, ..., S_n)/n$  is the arithmetic mean of the n first terms of the series  $H(S_1), H(S_2|S_1), ..., H(S_n|S_1, ..., S_{n-1})$ . Cesaro's theorem yields the expected result.

Cesaro's theorem. If  $a_n \xrightarrow[n \to \infty]{} a$ , then  $\frac{1}{n} \sum_{k=1}^n a_k \xrightarrow[n \to \infty]{} a$ 

Entropy of a stationary source

**Example 1.** In the case of a memoryless source, characterized by independent and identically distributed  $S_i$ , we have:

$$H_0 = H(S_1).$$

**Example 2.** If S denotes a time-invariant Markov source, its entropy is given by:

$$H_0 = H(S_2|S_1).$$

H(Sn/Sn-1) =

H(X

stationary and markov

 $H0 = \lim H(S2/S1,S2.....Sn-1)$ 

# SOURCE CODING

#### Definitions

Source coding consists of associating to each symbol  $s_i$  generated by a source, a sequence of symbols of a q-ary alphabet, referred to as a codeword.

Example 1. ASCII (7 bits) et extended ASCII (8 bits), Morse code, etc.

all have same lengtha nd we can decode all those combinations

Example 2.				0/01/0111 s1/s2/s4				
		code A	code B	code C	code D	code E	code F	code G
	$s_1$	1 /	/0 /	00	0 /	0	0	0
	$s_2$	1/	10	11	10/	01	10	10
	$s_3$	0	01	10	1/1	011	110	110
	$s_4$	0	11	01	110	0111	1110	111
s1s2 =s3s1 = 010 so its not good as we cant decode the result								

#### SOURCE CODING

#### Definition

different

**Regularity.** A code is said to be nonsingular if all codewords are distinct.

#### Decodability.

A nonsingular code is called uniquely decodable if any sequence of codewords can be decoded only in a unique way.

**Fixed length.** With fixed-length codewords, any message can be decoded without ambiguity.

**Separator.** A symbol of the alphabet is used as a word separator.

Without prefix. A code is called a prefix code or an instantaneous code if no codeword is a prefix of any other codeword.

**Exercise.** Characterize codes A to G.

Kraft's inequality

We propose to design uniquely decodable codes, and more particularly instantaneous codes, that are as compact as possible.

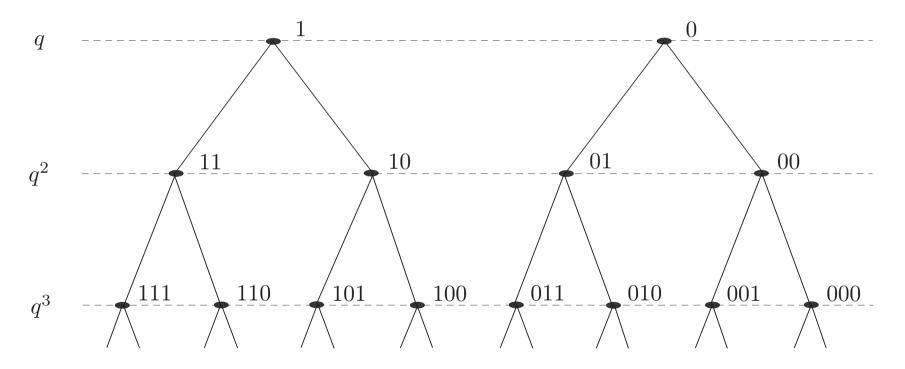

Kraft's inequality provides a necessary and sufficient condition on the existence of instantaneous codes for given codeword lengths.

**Theorem 1** (Kraft's inequality). Let  $n_1, \ldots, n_Q$  be candidate codeword lengths to encode the Q symbols of a source with a q-ary alphabet. A necessary and sufficient condition for the existence of an **instantaneous** code with these codeword lengths is given by:

**Remark.** The same necessary and sufficient condition was established by McMillan for uniquely decodable codes, previously to Kraft's inequality.

Kraft's inequality

**Proof.** The following representation, in the case of a binary code, makes the proof clear.

Kraft's inequality

Let  $n_1 \leq \ldots \leq n_Q$ . Consider a q-ary tree of height  $n_Q$ . This tree then has  $q^{n_Q}$  leaf nodes.

**Necessary condition.** The prefix condition requires that a codeword of length  $n_i$  excludes  $q^{n_Q-n_i}$  leaf nodes. Therefore, the total number of excluded leaf nodes must satisfy:

$$\sum_{i=1}^{Q} q^{n_Q - n_i} \le q^{n_Q}.$$

#### Sufficient condition.

First, we select a node with depth  $n_1$ , which excludes  $q^{n_Q-n_1}$  leaf nodes. However, there are still available leaf nodes because, using Kraft's inequality, we know that

$$q^{n_Q - n_1} < q^{n_Q}$$

On the way to one of the available leaf nodes, we select a node with depth  $n_2$ , ...

McMillan's inequality

Kraft's inequality implies that McMillan's inequality is sufficient since any prefix code is uniquely decodable.

**Necessary condition.** Consider the following expansion:

$$\left(\sum_{i=1}^{Q} r_i \, q^{-i}\right)^N = \sum_{n=1}^{NQ} \nu(n) \, q^{-n}$$

where  $\nu(n) = \sum_{i_1 + \dots i_N = n} r_{i_1} \dots r_{i_N}$ . Interpreting  $r_i$  as the number of codewords of length  $i, \nu(n)$  corresponds to the number of messages of length n. The unique decodability condition implies that  $\nu(n) \leq q^n$ . Then we have:

$$\sum_{i=1}^{Q} r_i \, q^{-i} \le (NQ)^{\frac{1}{N}},$$

which leads to the result by considering the limit of the upper bound when N tends to infinity.

McMillan's inequality

**Definition 8** (Complete code). A code is complete if:

$$\sum_{i=1}^{Q} q^{-n_i} = 1.$$

McMillan's inequality

As an example, McMillan's inequality is applied to different codes.

n: 12					
	code A	code B	code C	\ \\	
$s_1$	00	0	0		
$s_2$	01	100	10		
$s_3$	10	110	110		
S4	11	111	11		
$\sum_{i=1}^{4} 2^{-n_i}$	1	7/8	9/8		

Codes A and B are uniquely decodable, the first one being complete. Code C is not uniquely decodable.

Consequences of McMillan's inequality

Let S be a memoryless source with Q symbols. Let  $p_i$  be the probability of symbol  $s_i$ , encoded to a q-ary codeword of length  $n_i$ . By setting:

$$q_i = \frac{q^{-n_i}}{\sum_{j=1}^{Q} q^{-n_j}},$$

then applying Gibb's inequality with  $p_i$  and  $q_i$ , we obtain:

$$\sum_{i=1}^{Q} p_i \log \frac{1}{p_i} + \sum_{i=1}^{Q} p_i \log q^{-n_i} \le \log \sum_{i=1}^{Q} q^{-n_i}.$$

Applying McMillan's inequality to the right-hand side member of the inequality yields:

$$H(S) - \overline{n}\log q \le \log \sum_{i=1}^{Q} q^{-n_i} \le 0,$$

where  $\overline{n} = \sum_{i=1}^{Q} p_i n_i$  is the expected length of the codewords.

Consequences of McMillan's inequality

**Theorem 2.** The expected length  $\overline{n}$  of the codewords of any uniquely decodable code is lower-bounded by:

 $\frac{H(S)}{\log q} \le \overline{n}.$ 

Condition of equality. The above inequality turns into an equality if  $\sum_{i=1}^{Q} q^{-n_i} = 1$ , that is,  $p_i = q^{-n_i}$ . This means that:

$$n_i = \frac{\log \frac{1}{p_i}}{\log q}.$$

**Definition 9.** Any code where each codeword i is of length  $n_i = \frac{\log \frac{1}{p_i}}{\log q}$  is absolutely optimal.

Consequences of McMillan's inequality

Usually, the above equality condition is not satisfied because  $n_i = \frac{\log \frac{1}{p_i}}{\log q}$  is not an integer. However, it is possible to construct a code such that:

$$\frac{\log \frac{1}{p_i}}{\log q} \le n_i < \frac{\log \frac{1}{p_i}}{\log q} + 1.$$

Multiplying each member by  $p_i$  and summing over i, we obtain:

$$\frac{H(S)}{\log q} \le \overline{n} < \frac{H(S)}{\log q} + 1.$$

**Definition 10** (Shannon's code: predefined codeword lengths). We talk about a

Shannon's code when:

$$n_i = \left\lceil \frac{\log \frac{1}{p_i}}{\log q} \right\rceil.$$

# SHANNON'S FIRST THEOREM

#### Statement and demonstration

The bounds that have just been established will allow us to demonstrate Shannon's first theorem, which reads as follows:

**Theorem 3.** For any stationary source, there is a coding process to design a uniquely decodable code where the expected codeword length is as close to its lower bound as you want it to be.

**Proof in the case of a memoryless source.** Consider the  $k^{\text{th}}$  extension of source S. In the case of a memoryless source:

$$\frac{kH(S)}{\log q} \le \overline{n}_k < \frac{kH(S)}{\log q} + 1.$$

In this expression,  $\overline{n}_k$  denotes the expected length of the codewords used to encode the  $k^{\text{th}}$  extension of source S. Dividing by k and calculating the limit as k tends to infinity leads to the result.

### Premier théorème de Shannon

énoncé et démonstration

**Proof in the case of a stationary source.** Consider the  $k^{\text{th}}$  extension of a source S. In the case of a memoryless source, we have:

$$\frac{H(S_1, \dots, S_k)}{k \log q} \le \frac{\overline{n}_k}{k} < \frac{H(S_1, \dots, S_k)}{k \log q} + \frac{1}{k}.$$

In this expression,  $\overline{n}_k$  denotes la longueur denotes the expected length of the codewords used to encode the  $k^{\text{th}}$  extension of source S.

In the case of a stationary source, we know that  $\lim_{k\to\infty} H(S_1,\ldots,S_k)$  exists. Denoting this limit by  $H_0$  yields:

$$\lim_{k \to \infty} \frac{\overline{n}_k}{k} = \frac{H_0}{\log q}.$$

Shannon's code: predefined codeword length

Shannon's first theorem provides an asymptotic property, but do not provide any practical method for doing so.

Shannon's coding technique consists of associating  $n_i$  q-ary symbols to each source

state  $s_i$ , where:

$$n_i = \left\lceil \frac{\log \frac{1}{p_i}}{\log q} \right\rceil$$

Shannon's code: predefined codeword length

We consider a 5-symbol source  $\{s_1, \ldots, s_5\}$  defined by probabilities:

$$p_1 = 0.35$$
  $-\log_2 p_1 = 1.51$   $\longrightarrow$   $n_1 = 2$   
 $p_2 = 0.22$   $-\log_2 p_2 = 2.18$   $\longrightarrow$   $n_2 = 3$   
 $p_3 = 0.18$   $-\log_2 p_3 = 2.47$   $\longrightarrow$   $n_3 = 3$   
 $p_4 = 0.15$   $-\log_2 p_4 = 2.73$   $\longrightarrow$   $n_4 = 3$   
 $p_5 = 0.10$   $-\log_2 p_5 = 3.32$   $\longrightarrow$   $n_5 = 4$ .

We can easily get an instantaneous code that satisfies the above conditions on  $n_i$  using a tree. For instance:

$$s_1:00$$
  $s_2:010$   $s_3:011$   $s_4:100$   $s_5:1010$ .

This leads to  $\overline{n} = 2.75$ , to be compared to H(S) = 2.19 Sh/symb.

Shannon-Fano's code

Shannon-Fano's code is the first code that started to exploite the redundancy of a source. Its principle is now outlined.

- 1. Arrange the states of the system by decreasing probabilities.
- 2. Split the system states into 2 groups  $G_0$  et  $G_1$  with probabilities as close as possible without *modifying* their arrangement in 1.
- 3. Each group  $G_i$  is split into 2 sub-groups  $G_{i0}$  et  $G_{i1}$  with probabilities as close as possible to each other, again without modifying the state arrangement.
- 4. The procedure stops when each subgroup consists of a single element. The index of the group gives the codeword.

Shannon-Fano's code

To design a Shannon-Fano's code, we proceed as follows:

state	$p_i$	step 1	step 2	step 3	code
$s_1$	0.35	0	0		00
$s_2$	0.22	0	1		01
$s_3$	0.18	1	0		10
$s_4$	0.15	1	1	0	110
$s_5$	0.10	1	1	1	111

This leads to  $\overline{n} = 2.25$ , to be compared to H(S) = 2.19 Sh/symb.

Huffman's code

Huffman's method provides a compact instantaneous code of minimum average length. To achieve this, it exploits the following property.

**Lemme 1.** For any source, there is an instantaneous code of minimum expected length that satisfies the following properties.

- 1. If  $P(S = s_i) > P(S = s_j)$ , then  $n_i \le n_j$ .
- 2. The two longest words, therefore associated with the least likely states, have the same length and differ by only one bit.

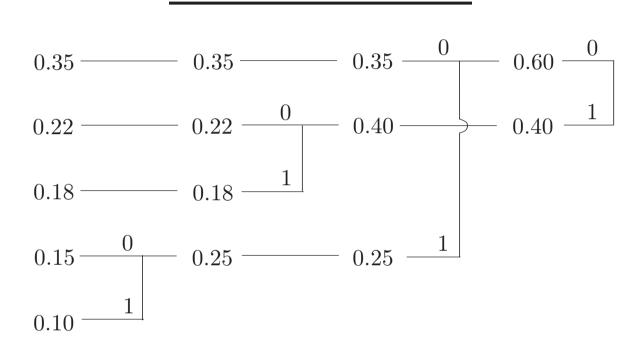

Huffman's method involves grouping the two least likely states together and then treating them as one by summing their probabilities. This technique is then repeated on the remaining states until only two remain.

#### Huffman's code

A tree is built from the leaf nodes, which represent the states of the source.

- 1. At each step, the two least likely leaves are merged into one.
- 2. The procedure stops when the result is a single leaf consisting of all the symbols.
- 3. The reverse path of the tree provides the code words.

Huffman's code

The reverse exploration of the tree provides the following code words:

 $s_1:00$   $s_2:10$   $s_3:11$   $s_4:010$   $s_5:011$ .

This leads to  $\overline{n} = 2.25$ , to be compared to H(S) = 2.19 Sh/symb.
